

8 The Optimizer

The optimizer component of `SECONDO` is written in `PROLOG` and allows one to formulate `SECONDO` commands as well as queries in an SQL-like language within a `PROLOG` environment. Commands are passed directly to the `SECONDO` kernel for execution. Queries are translated to query plans which are then also sent to the kernel for execution. One can also experiment with the optimizer and just see how queries are translated without executing them.

In the following sections after some preparations we discuss the `PROLOG` environment, the query language, hybrid queries (combining SQL with `SECONDO` operations) and creation of objects from query results, the optimizer's knowledge about databases, and how the optimizer can be informed about new operators available in `SECONDO`.

8.1 Preparations

In the following examples, we work with the database `opt`. Hence, enter at any of the user interfaces (e.g. in `SecondoTTYBDB`) the commands:

```
create database opt
restore database opt from opt
```

Now the database is in good shape. When you type `list objects`, you can see that it has the following relations:¹

```
Orte(Kennzeichen: string, Ort: string, Vorwahl: string, BevT: int)
Staedte(SName: string, Bev: int, PLZ: int Vorwahl: string,
  Kennzeichen: string)
plz(PLZ: int, Ort: string)
ten(no: int)
thousand(no:int)
```

Furthermore, for each of these relations called `x` there is another one with the same schema called `x-sample`. Finally, there are the two indexes `plz_Ort` and `plz_PLZ` which index on the `plz` relation the attributes `Ort` and `PLZ`, respectively. All relations are small except for `plz` which is a bit larger, having 41267 tuples.

8.2 Using `SECONDO` in a `PROLOG` environment

In Section 5 it was already discussed how the optimizer can be called. In this section, we assume that the single user version `SecondoPL` is used; the client-server interface `SecondoPLCS` behaves similarly. Hence, switch to the directory `Optimizer` and call the optimizer by the command:

```
SecondoPL
```

After some messages, there appears a `PROLOG` prompt:

```
1 ?-
```

1. There is also a further relation `SEC_DERIVED_OBJ` used internally to restore indexes and other derived objects.

When the optimizer is used for the first time after installing `SECONDO`, some error messages appear; these can safely be ignored. The reason is that some files generated by the running optimizer are not yet there.

We now have a `PROLOG` interpreter running which understands an additional predicate:

```
secondo(Command, Result) :- execute the Secondo command Command and get
                             the result in Result.
```

So at the command line, one can type:

```
1 ?- secondo('open database opt', Res).
```

This is executed, some `SECONDO` messages appear, and then the `PROLOG` interpreter shows the result of binding variable `Res`:

```
Res = []
```

This is the empty list that `SECONDO` returns on executing successfully such a command, converted to a `PROLOG` list. As usual with a `PROLOG` interpreter we can type `<return>` to see more solutions, to which the interpreter responds

```
Yes
2 ?-
```

Let us try another command:

```
2 ?- secondo('query Staedte feed filter[.Bev > 500000] head[3]
| consume', R), R = [First, _].
```

Here at the end of the first line we typed `<return>`, the interpreter then put “|” “at the beginning of the next line. The `PROLOG` goal is complete only with the final “.” symbol, only then interpretation is started. Here as a result we get after some `SECONDO` messages the result of the query shown in variable `R` and the first element in variable `First`. This illustrates that, of course, we can process `SECONDO` results further in the `PROLOG` environment.

By the way, when you later want to quit the running `SecondoPL` program, just type at the prompt:

```
.. ?- halt.
```

In the sequel, we omit the `PROLOG` prompt in the examples.

There is also a version of the `secondo` predicate that has only one argument:

```
secondo(Command) :- execute the Secondo command Command and pretty-print
                     the result, if any.
```

Hence we can say:

```
secondo('query Staedte').
```

The result is printed in a similar format as in `SecondoTTYBDB` or `SecondoTTYCS`.

In addition, a number of predicates are available that mimic some frequently used `SECONDO` commands, namely

```
open
create
update
```

```
let
delete
query
```

They all take a character string as a single argument, containing the rest of the command, and are defined in PROLOG to be prefix operators, hence we can write:

```
secondo('close database').
open 'database opt'.
create 'x: int'.
update 'x := Staedte feed count'.
let 'double = fun(n: int) 2 * n'.
query 'double(x)'.
delete 'x'.
```

8.3 An SQL-like Query Language

The optimizer implements a part of an SQL-like language by a predicate `sql`, to be written in prefix notation, and provides some operator definitions and priorities, e.g. for `select`, `from`, `where`, that allow us to write an SQL query directly as a PROLOG term. For example, one can write (assuming database `opt` is open):

```
sql select * from staedte where bev > 500000.
```

Note that in this environment all relation names and attribute names are written in lower case letters only. Remember that words starting with a capital are variables in PROLOG; therefore we cannot use such words. The optimizer on its own gets information from the `SECONDO` kernel about the spellings of relation and attribute names and sends query plans to `SECONDO` with the correct spelling.

Some messages appear that tell you something about the inner workings of the optimizer. Possibly the optimizer sends by itself some small queries to `SECONDO`, then it says:

```
Destination node 1 reached at iteration 1
Height of search tree for boundary is 0

The best plan is:

Staedte feed filter[.Bev > 500000] consume

Estimated Cost: 120.64
```

After that appears the translation of the query into nested list format by `SECONDO`, evaluation messages, and the result of the query. If you are interested in understanding how the optimizer works, please read the paper [GBA+04]. If you wish to understand the working of the optimizer in more detail, you can also read the source code documentation, that is, say in the directory `Optimizer`:

```
make
pdview optimizer
pdprint optimizer
```

In the following, we describe the currently implemented query language in detail. Whereas the syntax resembles SQL, no attempt is made to be consistent with any particular SQL standard.

Basic Queries

The SQL kernel implemented by the optimizer basically has the following syntax:

```
select <attr-list>
from <rel-list>
where <pred-list>
```

Each of the lists has to be written in PROLOG syntax (i.e., in square brackets, entries separated by comma). If any of the lists has only a single element, the square brackets can be omitted. Instead of an attribute list one can also write “*”. Hence one can write (don’t forget to type `sql` before all such queries):

```
select [sname, bev]
from staedte
where [bev > 270000, sname starts "S"]
```

To avoid name conflicts, one can introduce explicit variables. In this case one refers to attributes in the form `<variable>:<attr>`. For example, one can perform a join between relations `orte` and `plz`:

```
select * from [orte as o, plz as p]
where [o:ort = p:ort, o:ort contains "dorf", (p:plz mod 13) = 0]
```

In the sequel, we define the syntax precisely by giving a grammar. For the basic queries described so far we have the following grammar rules:

query	->	select sel-clause from rel-list where-clause
sel-clause	->	* result-list
result	->	attr attr-expr as newname
attr	->	attrname var:attrname
rel	->	relname relname as var
where-clause	->	where pred-list empty
pred	->	attr-boolexpr

We use the following notational conventions. Words written in normal font are grammar symbols (non-terminals), words in bold face are terminal symbols. The symbols “->” and “|” are meta-symbols denoting derivation in the grammar and separation of alternatives. Other characters like “*” or “:” are also terminals.

The notation *x-list* refers to a non-empty PROLOG list with elements of type *x*; as mentioned already, the square brackets can be omitted if the list has just one element.

The notation *x-expr* refers to an expression built from elements of type *x*, constants, and operations available on *x*-values. Hence *attr-expr* is an expression involving attributes denoted in one of the two forms *attrname* or *var:attrname*. Similarly a predicate (*pred*) is a boolean expression over attributes.

Finally, *empty* denotes the empty alternative. Hence the where-clause is optional.

From the grammar, one can see that it is also possible to compute derived attributes in the select-clause. For example:

```
select [sname, bev div 1000 as bevt] from staedte
```

Order

One can add an orderby-clause (and a first-clause, see below), hence the syntax of a query is more completely:

```
query          -> select sel-clause from rel-list where-clause  
                orderby-clause first-clause
```

```
orderby-clause -> orderby orderattr-list  
                | empty
```

```
orderattr      -> attrname | attrname asc | attrname desc
```

For example, we can say:

```
select [o:ort, p1:plz, p2:plz]  
from [orte as o, plz as p1, plz as p2]  
where [o:ort = p1:ort, p2:plz = (p1:plz + 1), o:ort contains "dorf"]  
orderby [o:ort asc, p2:plz desc]
```

It is possible to mention derived attributes in the orderby-clause.

Taking Only the First n Elements

Sometimes one is interested in only the first few tuples of a query result. This can be achieved by using a first-clause:

```
first-clause    -> first int-constant  
                | empty
```

For example:

```
select * from plz orderby ort desc first 3
```

This is also a convenient way to see the beginning of a large relation. Only the first few tuples are processed.

Grouping and Aggregation

Aggregation queries have a groupby-clause in addition to what is known already and a different form of the select-clause.

```
query          -> select aggr-list from rel-list where-clause  
                groupby-clause orderby-clause first-clause
```

```
aggr           -> groupattr | count(*) as newname  
                | aggrop(attr-expr) as newname
```

```
groupattr      -> attr
```

```
aggrop         -> min | max | sum | avg
```

groupby-clause -> **groupBy** attr-list

For example, one can say:

```
select [ort, min(plz) as minplz, max(plz) as maxplz, count(*) as cntplz]
from plz
where plz > 40000
groupBy ort
orderBy cntplz desc
first 10
```

Entries in the select-clause are either attributes used in the grouping or definitions of derived attributes which are obtained by evaluating aggregate functions on the group. Again one can order by such derived values. An aggregate operator like `sum` cannot only be applied to an attribute name, but also to an expression built over attributes.

There is one restriction imposed by the current implementation and not visible in the grammar: the select-clause in an aggregate query must contain a derived attribute definition. Hence

```
select ort from plz groupby ort
```

will not work. This will be optimized but not executed by `SECONDO`.

Union and Intersection

It is possible to form the union or intersection of a set of relations each of which is the result of a separate query. The queries are written in a `PROLOG` list. All result relations must have the same schema.

```
mquery          ->  query
                  |  union query-list
                  |  intersection query-list
```

For example:

```
union [
  select * from plz where ort contains "dorf",
  select * from plz where ort contains "stadt"]
```

Note that in this case, each of the subqueries in the list is optimized separately. One interesting application is to find tuples in a relation fulfilling a very large set of conditions. The optimizer's effort in optimizing a single query is exponential in the number of predicates. It works fine roughly up to 10 predicates. Beyond that optimization times get long. However, it is no problem to use, for example, an intersection query on 30 subqueries each of which has only one or a few conditions.

The query processed by the optimizer is an `mquery`, i.e., the query command is of the form

```
sql mquery
```

The complete grammar can be found in Appendix B.

8.4 Further Ways of Querying

The basic form of querying is using the `sql` predicate in prefix notation, as explained in the previous section, hence

```
sql Term
```

Hybrid Queries

A second form of the `sql` predicate allows one to further process the result of a query by `SECONDO` operators:

```
sql(Term, SecondoQueryRest)
```

Here `SecondoQueryRest` contains a character string with `SECONDO` operators, applicable to a stream of tuples returned by the optimized and evaluated `Term`. For example:

```
sql(select * from orte where bevt > 300, 'project [Ort] consume').
```

Note that in the second argument, attribute names have to be spelled correctly as in writing executable queries to the `SECONDO` kernel. In this example, the same effect could have been achieved by a pure SQL query, but there are cases when this facility is useful.

Creating Objects

The `let` command of `SECONDO` allows one to create `SECONDO` objects as the result of an executable query. There is a `let` predicate in the optimizer that allows one to do the same for the result of an optimized query. There are two forms, the second one corresponding to a hybrid query.

```
let(ObjectName, Term)
let(ObjectName, Term, SecondoQueryRest)
```

For example:

```
let(orte2, select ort from [orte, plz as p] where ort = p:ort orderby ort,
'rdupe consume').
```

This query creates a relation `orte2` with the names of places (“Orte”) that also occur in the postal code relation `plz`. Since duplicate removal is currently not implemented in the SQL language, it is added here using a hybrid query.

Just Optimizing

For experimenting with the optimizer it is useful to optimize queries without executing them. This is provided by the `optimize` predicate.

```
optimize(Term)
```

This returns the query plan and the expected cost.

8.5 The Optimizer’s Knowledge of Databases

The optimizer and the SECONDO kernel are only loosely coupled. In particular, one can use the kernel independently, create and delete databases and objects within databases out of control of the optimizer.

The optimizer maintains knowledge about the existing database contents within a number of “dynamic predicates” while the optimizer is running, and in files between sessions. It obtains such knowledge from the SECONDO kernel by sending commands or queries to it, for example, `list objects`. Currently there are six such predicates and corresponding files:

- *storedRels* - relations and their attributes
- *storedSpells* - spellings of relation and attribute names
- *storedIndexes* - for which attributes do and do not exist indexes
- *storedCards* - cardinalities of relations
- *storedTupleSizes* - average tuple sizes (in bytes) of relations
- *storedSels* - selectivities of selection and join predicates

The optimizer currently does not distinguish between different databases. Hence, if there are different databases having relations with the same name but different properties, the optimizer may get confused. This should be avoided at the current stage of implementation.²

The general principle is that the optimizer retrieves information from SECONDO when it is needed and then stores it for later use. For example, when a relation is mentioned for the first time in a query, the optimizer sends “`list objects`” to the kernel to check whether the relation exists and to get attribute names with their spelling. It also determines whether there are indexes available and creates a small sample relation if there is none yet. It sends a query “`<relname> count`” to get the cardinality and another “`<relname> tuplesize`” to get the average tuple size in byte.

When in a query a selection or join predicate occurs for which the selectivity is not yet known, the optimizer sends a corresponding query on the small sample relation(s) to determine the selectivity.

Note: The optimizer recognizes indexes by a name convention. The name of the index must have the form `<relation name>_<attribute name>`. These names must be spelled as in the SECONDO kernel except that the first letter must be in lower case (due to its use in PROLOG). Hence an index on attribute `Bev` of relation `Staedte` must be called `staedte_Bev` to be recognized by the optimizer. Such an index can be created by the command:

```
let 'staedte_Bev = Staedte createbtree[Bev]'.
```

Reinitializing

One can reinitialize the optimizer’s knowledge of databases by deleting the six files `storedRels` etc. mentioned above from the directory `Optimizer` (when the optimizer is not running). In this case, all information needed will be collected afresh on further queries.

2. Of course, this is a problem that should be addressed in the optimizer implementation.

Creating and Deleting Relations

When new relation objects are created, the optimizer should recognize them automatically as soon as they are used in a query. However, the optimizer will not automatically be aware that a relation has been deleted and will still create query plans for it which will then be refused by the SECONDO kernel. We explain below how the optimizer can be informed about the deletion.

Creating and Deleting Indexes

The optimizer checks for indexes when a relation is mentioned for the first time in a query. Hence, it automatically recognizes indexes created together with a relation before querying. However, once it has been determined that for a given attribute of a relation no index exists, the optimizer will not check further for an index on that attribute. The optimizer also does not notice when an index is deleted.

Informing the Optimizer

Two commands (predicates) are available to explicitly inform the optimizer about changes to relations and indexes.

```
updateRel (Rel)
```

A call of this predicate causes the optimizer to delete all information it has about the relation `Rel`, including selectivities of predicates. An existing sample is also destroyed. A query afterwards involving this relation collects all information from scratch. Existing or non-existing indexes are also discovered. For example:

```
updateRel (plz) .
```

resets all information for relation `plz`. The second predicate is:

```
updateIndex (Rel, Attr)
```

This predicate lets the optimizer only check whether an index exists on `Rel` for `Attr`. Hence this can be used after creating or destroying an index, without losing all the other information collected for relation `Rel`. For example, after deleting the index `plz_Ort` one should inform the optimizer by saying:

```
updateIndex (plz, ort) .
```

8.6 Operator Syntax

In queries given to the optimizer one uses atomic operators in predicates and expressions in the select-clause like

```
<, >, <=, #, starts, contains, +, *, div, mod
```

In this section we explain how new operators of this kind can be made available in the optimizer. For using operators in queries, there are two conditions:

1. We must be able to write the operator in PROLOG.
2. The optimizer must know how to translate the operator application to SECONDO syntax.

PROLOG Syntax

Any operator can be written in PROLOG in prefix syntax. For example:

```
length(X), theDate(2004, 5, 9)
```

These are just standard terms in PROLOG. If we want to write a (binary) operator in infix notation, either this operator is defined already in PROLOG. This is the case for standard operators like `+`, `*`, `<`, etc. Otherwise one can explicitly define it in the file `opsyntax.pl` in directory `Optimizer`. For example, in the file we find definitions:

```
:- op(800, xfx, inside).
:- op(800, xfx, intersects).
:- op(800, xfx, touches).
:- op(800, xfx, or).
:- op(800, fx, not).
```

Here `inside`, `intersects`, `touches`, and `or` are defined to be binary infix operators, and `not` is defined to be a unary prefix operator. New operators can be made available in the same way.

SECONDO Syntax

Translation to SECONDO is controlled firstly, by a few defaults, depending on the number of arguments:

- one argument: translated to prefix notation
`op(arg)`
- two arguments: translated to infix notation
`arg1 op arg2`
- three arguments: translated to prefix notation
`op(arg1, arg2, arg3)`

If a binary operator is to be translated to prefix notation instead, one can place a fact into the file `opsyntax.pl` of the form

```
secondoOp(Op, prefix, 2)
```

For example, to define a `distance` operator with two arguments to be written in prefix notation we can specify:

```
secondoOp(distance, prefix, 2).
```

Reload the file after modifying it:

```
[opsyntax].
```

The current contents of the file are shown in Appendix A. For example, we can now use the `distance` operator in a query (on a database `germany`):

```
select [sname, distance(ort, s2:ort) as dist]
from [stadt, stadt as s2]
where [s2:sname = "Dortmund", distance(ort, s2:ort) < 0.3]
```

A Operator Syntax

```

/*
1 Operator Syntax

[File ~opsyntax.pl~]

*/

:-
    op(800, xfx, =>),
    op(800, xfx, <=),
    op(800, xfx, #),
    op(800, xfx, div),
    op(800, xfx, mod),
    op(800, xfx, starts),
    op(800, xfx, contains),
    op(200, xfx, :).

:- op(800, xfx, inside).
:- op(800, xfx, intersects).
:- op(800, xfx, touches).
:- op(800, xfx, or).
:- op(800, fx, not).

/*

----secondoOp(Op, Syntax, NoArgs) :-
----

~Op~ is a Secondo operator written in ~Syntax~, with ~NoArgs~ arguments.
Currently implemented:

    * postfix, 1 or 2 arguments: corresponds to _ # and _ _ #

    * postfixbrackets, 2 or 3 arguments, of which the last one is put into
the brackets: _ # [ _ ] or _ _ # [ _ ]

    * prefix, 2 arguments: # (_, _)

    * prefix, either 1 or 3 arguments, does not need a rule here, is
translated by default.

    * infix, 2 arguments: does not need a rule, translated by default.

For all other forms, a plan_to_atom rule has to be programmed explicitly.

*/

secondoOp(distance, prefix, 2).

secondoOp(feed, postfix, 1).
secondoOp(consume, postfix, 1).
secondoOp(count, postfix, 1).
secondoOp(product, postfix, 2).
secondoOp(filter, postfixbrackets, 2).
secondoOp(loopjoin, postfixbrackets, 2).
secondoOp(exactmatch, postfixbrackets, 3).

```

```
secondoOp(leftrange, postfixbrackets, 3).
secondoOp(rightrange, postfixbrackets, 3).

```

B Grammar of the Query Language

We use the following notational conventions. Words written in normal font are grammar symbols (non-terminals), words in bold face are terminal symbols. The symbols “->” and “|” are meta-symbols denoting derivation in the grammar and separation of alternatives. Other characters like “*” or “:” are also terminals.

The notation *x-list* refers to a PROLOG list with elements of type *x*; as mentioned already, the square brackets can be omitted if the list has just one element. The notation *x-expr* refers to an expression built from elements of type *x*, constants, and operations available on *x*-values. Hence *attr-expr* is an expression involving attributes denoted in one of the two forms *attrname* or *var:attrname*. Similarly a predicate (*pred*) is a boolean expression over attributes. Finally, *empty* denotes the empty alternative. For example, the where-clause is optional.

```
query          ->  select sel-clause from rel-list where-clause
                  orderby-clause first-clause
                  |  select aggr-list from rel-list where-clause
                  groupby-clause orderby-clause first-clause

sel-clause     ->  * | result-list

result        ->  attr | attr-expr as newname

attr          ->  attrname | var:attrname

rel           ->  relname | relname as var

where-clause  ->  where pred-list
                  |  empty

pred          ->  attr-boolexpr

orderby-clause ->  orderby orderattr-list
                  |  empty

orderattr     ->  attrname | attrname asc | attrname desc

first-clause  ->  first int-constant
                  |  empty

aggr          ->  groupattr | count(*) as newname
                  |  aggroup(attr-expr) as newname
```

```
groupattr      -> attr
aggrop         -> min | max | sum | avg
groupby-clause -> groupby attr-list
mquery         -> query
                | union query-list
                | intersection query-list
```
